Digital Collateral*

Paul Gertler†  Brett Green‡  Catherine Wolfram§

March 9, 2022

Abstract

A new form of secured lending utilizing “digital collateral” has recently emerged, most prominently in low and middle income countries. Digital collateral relies on “lockout” technology, which allows the lender to temporarily disable the flow value of the collateral to the borrower without physically repossessing it. We explore this new form of credit both in a model and in a field experiment using school-fee loans digitally secured with a solar home system. We find that securing a loan with digital collateral drastically reduces default rates (by 19 pp) and increases the lender’s rate of return (by 38 pp). Employing a variant of the [Karlan and Zinman (2009)] methodology, we decompose the total effect on repayment and find that roughly one-third is attributable to adverse selection and two-thirds is attributable to moral hazard. In addition, we find that access to digitally-secured school-fee loans significantly increases school enrollment (by 8 pp) and school-related expenditures (by 42%) without detrimental effects to households’ balance sheet.

1 Introduction

There is a general consensus that households in low and middle income countries (LMICs) have insufficient access to credit. Twenty years ago economists were optimistic that microfinance would fill this void, yet most of the evidence suggests that microfinance loans do not have transformative effects on the average borrower (Banerjee et al., 2015; Meager, 2019). While microfinance remains the predominant source of credit to households at the bottom of the pyramid, microfinance institutions (MFIs) are struggling as the costs of making small loans to poor clients are high, in part due to mediocre repayment (Cull et al., 2018).

One reason that microfinance loans suffer from mediocre repayment is that they are typically unsecured. In contrast, more than 80% of total household debt in the US is secured by a physical asset. Using collateral to secure debt helps overcome economic frictions, thereby expanding the supply of credit and reducing the cost of credit provision. Yet, secured debt is much less prevalent in poor countries. Why? On the supply side, property rights are difficult to establish and enforce in economies with weak legal institutions, which translates to a high cost of repossessing collateral for creditors. This is especially true for households in remote areas, where the costs associated with locating, repossessing, and redeploying collateral are prohibitive. On the demand side, the primary source of income for many households in LMICs is self-employment, which is subject to more frequent shocks than formal sector wages. Lacking savings, these households are more likely to default for nonstrategic reasons and may choose

---

1Microfinance loans constituted roughly $124 billion in value to over 140 million individuals in 2018, which corresponded to an annual growth rate of 11.5% over the previous 5 years (Microfinance Barometer 2019, https://www.convergences.org/barometre-de-la-microfinance, date accessed Jan 6, 2022).

2Early on, MFIs used joint liability though group lending to help manage risk. However, group lending often involves frequent and time-consuming repayment meetings and exerts strong social pressure, making it onerous for borrowers. This is one of the main reasons why MFIs have started to move from joint to individual lending. In fact, a number of large well established MFIs have moved from group lending, as pioneered by the Bangladeshi Grameen bank in the 1970s, to individual lending including, for example, Grameen Bank II, ASA in Bangladesh and BancoSol in Bolivia (Cull et al., 2009).

to avoid the risk of having assets repossessed.

We will argue that collateral need not be physically repossessed in order to serve a useful role in credit markets, nor does repossessions need to be overly punitive. Recent technological innovations have facilitated the use of new form of collateral, which we refer to as digital collateral. An emerging example is pay-as-you-go financing (PAYGO). The typical PAYGO contract requires a nominal down payment to take possession of an asset, followed by frequent, small payments made via a mobile payment system. PAYGO financing crucially relies on an embedded “lockout technology” that allows the lender to remotely disable the flow of services from the asset. In other words, the lender can digitally repossess the asset without the need to repossess it physically. Digital collateral has several technological advantages: disabling the flow of services is cheap and easily reversible. Borrowers unable to make a payment do not lose the asset, rather they are simply unable to consume the flow of services from the asset until they start paying again. These advantages allow for a richer space of financial contracts involving flexible repayment schedules (e.g., pay per usage) and temporary (digital) repossession for non-payment.²

In this paper, we explore this new financial contract within a theoretical model and a field experiment. In particular, we investigate the extent to which credit secured with digital collateral has better repayment than unsecured debt, the most common form of debt in LMICs. In other words, since the market for credit secured with physical collateral effectively does not exist and unsecured credit suffers from poor repayment, we ask whether digitally secured credit is a feasible equilibrium contract. We then examine how access to this form of credit affects households.

**Theoretical Framework** In the model, firms can produce a good at a constant marginal cost. Households have a private value for consuming the good that is realized after they take possession of it. Due to their limited wealth and financial constraints, households cannot afford...

---

¹These features are in contrast to the typical secured loan that involves a fixed repayment schedule and permanent (physical) repossession in default.
to purchase the good outright. In order to recoup their costs, firms must offer financing to households. But households cannot credibly commit to repay out of future income. Thus, firms offer a contract that is collateralized by the good: if the household does not repay the loan then the firm repossesses the good.

Repossessing collateral plays two roles: (i) the lender recovers something of value, thereby insuring them against default, and (ii) the household loses something of value, thereby providing them incentive to repay the loan or decline the loan offer. In most models of collateralized lending, these two roles are inherently bundled. They need not be. In both our model and experimental setting, repossession via lockout implies a loss in value to households who fail to repay, but does not necessarily involve recovery value for the lender. This decoupling is especially valuable when lenders face a high cost of repossession rendering the recovery role of little (net) value.

Much like traditional collateral, securing loans with digital collateral reduces the firms’ cost of providing financing via two channels relative to unsecured credit. First, it provides households with an incentive to repay the loan when they can afford to do so, thereby mitigating the moral hazard problem of strategic default. Second, when combined with a downpayment, digital collateral serves as a screening mechanism to mitigate adverse selection. That is, a borrower that is more likely to face a negative income shock will have less incentive to accept a digitally secured loan. By reducing moral hazard and adverse selection, lenders can offer more financing to credit-worthy borrowers at terms they find acceptable.

In spite of the two aforementioned attributes, a more effective lockout technology—which enables collateral to be digitized—does not necessarily increase welfare. More effective lockout destroys more surplus (i.e., household utility) when it is utilized, which can offset the welfare gains of the credit expansion, even if it is utilized less frequently. As a result, an intermediate degree of lockout following non-repayment can be welfare maximizing. This finding is consistent
with the temporary and relatively lenient nature in which lockout is deployed in PAYGO contracts compared to traditional secured lending.

**Experimental Design**  We conduct a field experiment to identify the impact of digital collateral on market frictions and economic outcomes. We partnered with Fenix International, the largest solar-home system (SHS) provider in Uganda. An SHS provides a household with access to a modest amount of electricity without being connected to the grid. Fenix offers PAYGO financing for their SHS. They also offer follow-up loans for good payers, where the SHS is re-used as digital collateral to secure the loan. Our study examines the effects of digital collateral with Fenix’s most popular follow-up product: a cash loan that is offered to customers near the beginning of each school term when school fees are due.

Our experimental design randomizes the sample into three treatment groups and a control group. In the first treatment, the customer is offered a loan secured with digital collateral. In the second treatment, the customer is offered an unsecured loan. In the third treatment, a customer is offered a secured loan, but if this offer is accepted, the customer is (positively) “surprised” and receives an unsecured loan. The “surprise” group is used to disentangle adverse selection from moral hazard a la Karlan and Zinman (2009).

**Experimental Results**  Our experiment yields five main results. First, customer interest and take-up rates are high. More than 12% of the over 27,000 customers who received an SMS about the loan indicated they were interested. Of the 2,200 customers who were offered a loan after expressing interest, 47% accepted the offer and received a loan. These high take-up rates suggest the loan terms were attractive to customers and help to alleviate credit constraints.

---

5Technically, all of the loans originated by the lender include a provision for physical repossession if the borrower is sufficiently delinquent (more than 180 days). In practice, however, the lender almost never attempts a physical repossession because it is costly and ineffective. Therefore, the unsecured loans in our experiment are effectively unsecured.
Second, consistent with our hypothesis that digital collateral reduces adverse selection, the take-up rate was about 6 percentage points (pp) lower for customers offered a (digitally) secured loan than those offered an unsecured loan (45% vs 51%). The differential in take-up rates is statistically significant ($p = 0.004$).

Third, securing a loan with digital collateral significantly increases loan repayment. Average repayment increased by 11 pp when the loan was secured with digital collateral compared to an unsecured loan. Furthermore, the fraction of households that fully repaid the secured loan was 19 pp higher than the unsecured loans. From a profitability standpoint, unsecured loans were highly unprofitable. By securing loans with digital collateral, the (annualized) internal rate of return of lending increased by 38 pp. About two-thirds of the total increase in repayment can be attributed to (a reduction in) moral hazard, while one-third is driven by adverse selection. The reduction in moral hazard was concentrated among higher risk borrowers (based on repayment of previous loans), whereas the reduction in adverse selection was concentrated among lower risk borrowers.

Fourth, the school-fee loan increased both enrollment and school-related expenditures (i.e., school fees, uniforms, supplies, transport, and meals). Children in households that were offered a school-fee loan were significantly more likely to be enrolled at school compared to children in the control group. Accounting for loan take-up, the loans reduced the share of children who were not enrolled by half (from 12% to 6%). In addition, households with loans increased school-related expenditures by 34%. Increases in enrollment were concentrated among males, but increases in expenditures were observed for both males and females. The increases in enrollment and expenditures were modestly larger for the secured treatment group, but not statistically different from the other two treatment groups.

Fifth, the loans did not have significant effects on household balance sheets in any of the treatment groups. Asset purchases and sales remained largely unchanged. Total household
borrowing increased by about 60% of the school-fee loan commensurate with the increase in school expenditures, but the magnitude is not statistically significant.

**Discussion and Interpretation of Findings** Our findings with respect to profitability suggest that without digital collateral, firms would be unwilling to offer unsecured credit to households. Since the market for traditional secured loans is largely non-existent, digital collateral appears to be a feasible contract design that facilitates access to credit for large numbers of households. Therefore, we assess the welfare effects of access to credit using the control group as the counterfactual.

Our finding that moral hazard rather than adverse selection drives the majority of the repayment increase is important because it suggests that sustainable credit provision (i.e., contracts that firms are willing to offer) is acceptable to a large fraction of households, provided they are given the right incentives. Therefore, the potential for digital collateral to expand access to credit may be significant. By contrast, if we had found that most of the increase in repayment was due to adverse selection, then digital collateral serves primarily as a screening device and only a select subset of households are both willing and profitable lending opportunities.

Altogether, our results suggest that digital collateral increases the share of customers to whom a company can profitably offer loans. Moreover, these loans significantly increased school enrollment and expenditures, suggesting that the customers did not have access to other sources of financing to pay for school fees.

While these findings are suggestive of a welfare improvement, securing loans with digital collateral is not without cost. First, there are costs to produce and integrate the lockout technology, which leads to higher prices for customers. Second, there is the (ex-post) inefficiency associated with locking the devices. In our sample, the SHS was locked for 50 of the first 200 days from loan origination for the median household (Table 3). On one hand, this could be viewed as a feature
of the PAYGO contract; customers need not make payments on days in which they do not require electricity, whereas borrowers face permanent repossession if they fail to repay a traditional secured loan. On the other hand, it suggests that there is potential room for improvement in the contract design. We provide a more detailed discussion of the welfare implications in Section 7.3.

Our study helps to explain why digital collateral is being employed in a range of emerging applications. For example, PayJoy, a FinTech firm based in San Francisco, developed a lockout technology for smart phones and has been offering digitally secured credit for the purchase of smart phones since 2016. Similar to Fenix’s school-fee loan product, they now offer secured cash loans to customers who have completed the payments on the initial loan by recollateralizing the smart phone. Payjoy has large scale operations in Mexico, and a small but growing customer base in South Africa, India, Indonesia, and Zambia. With the proliferation of smart devices, secured lending via digital collateral could easily be extended to a wide range of devices such as laptops, refrigerators, and televisions. Importantly, the capacity to reuse collateral for future loans (as it has been by Fenix and PayJoy) expands the potential impact of the innovation as a vehicle for affordable access to credit.

A similar technology has been deployed in the United States for subprime auto loans. Several firms have developed starter interrupt devices, which allow the lender to remotely disable the ability to start the car if the borrower is not in good standing on the loan. These devices have been installed in more than two million vehicles. Electric, telecommunication, and water companies have been using similar contracts to finance last mile connection costs. In addition some utilities use their flow of services as digital collateral to provide financing for other asset purchases. For example, TELMEX, a Mexican telecom provides secured loans to customers for the purchase

---

6See https://dealbook.nytimes.com/2014/09/24/miss-a-payment-good-luck-moving-that-car
of computer equipment using the customers’ access to internet service as digital collateral. We believe there is significant potential for utilities to further scale the use of digital collateral in providing affordable access to credit in LMICs.

2 Related Literature

Our paper relates to several different literatures including the use of collateral in corporate and household finance, microfinance, and education in developing countries.

Collateral in Credit Markets There is a large theoretical literature explaining the use of collateral in credit markets. Our contribution to this literature is to explicitly model the repossession technology and to understand how its characteristics impact economic outcomes. Most relevant to our work are the numerous papers that have illustrated how collateral can be useful to mitigate inefficiencies associated with moral hazard, adverse selection, and limited enforcement. Bester (1985) shows that the credit rationing in Stiglitz and Weiss (1981) can be (partially) overcome through the use of collateral as a screening device: better credit risks post more collateral and receive a lower interest rate, thereby eliminating the need for rationing. Another explanation for the use of collateral is to alleviate moral hazard problems: posting collateral makes it more costly for a borrower to risk shift, shirk, or strategically default. Bester (1987), Chan and Thakor (1987), Tirole (2006).

An extensive empirical literature explores the role of collateral in credit markets. Consistent with our experimental findings, a number of papers have found observational evidence consistent

---

7 See https://telmex.com/web/hogar/credito-telmex.
8 Similar findings obtain in Chan and Kanatas (1989); Bester (1987); Besanko and Thakor (1987ab).
9 The theoretical literature also illustrates other roles for the use of collateral (or control rights) including incomplete contracts (Aghion and Bolton 1992; Hart and Moore 1994), monitoring incentives (Rajan and Winton 1995), priority (Ayotte and Bolton 2011), limited enforcement (Rampini and Viswanathan 2013), exclusivity (Donaldson et al. 2019), and as a commitment device (DeMarzo 2019).
with moral hazard (Berger and Udell 1990, 1995; Jimenez et al. 2006).

There is also evidence that a more efficient repossession technology facilitates an expansion of credit. One source of inefficiency are liquidation costs after repossession. Assunção et al. (2013) shows that loan spreads dropped and credit expanded, but default rates increased after a Brazilian reform that simplified the sale of repossessed cars. Benmelech and Bergman (2009) finds that debts secured by more redeployable collateral exhibit lower credit spreads, higher credit ratings, and higher loan-to-value ratios. Another source of inefficiency are the costs associated with repossessing collateral after default due to weak creditor rights. In countries with stronger creditor rights protection (and thus lower costs of repossession), the credit markets are more developed, which may contribute to economic growth (e.g., La Porta et al. 1998; Qian and Strahan 2007; Djankov et al. 2007). The potential economic benefits of digital collateral are therefore more significant in less developed countries and countries with weaker creditor rights protection (Liberti and Mian 2010; Benmelech et al. 2020).

Existing literature has shown that there are trade-offs associated with secured borrowing. Exhausting pledgeable assets may mean losing financial flexibility and giving up profitable future investment opportunities (see, e.g., Acharya et al. 2007; Rampini and Viswanathan 2010, 2013; Li et al. 2016; Donaldson et al. 2019). By pledging collateral, a firm also limits its flexibility to sell or redeploy assets to craft a better business operation. Indeed, Benmelech et al. (2020) document a significant decline in secured debt (as a fraction of total debt) among US firms over the twentieth century attributed in part to these reasons.

While secured lending is uncommon in LMICs, one recent study uses a field experiment to study the potential for asset collateralization to expand access to credit in rural Kenya. Jack et al. (2019) find that a reduction in the down payment on a water tank from 25% to 4% led to a significant increase in take-up with only a modest increase in default rates, which they
attribute almost entirely to adverse selection rather than moral hazard. This is in contrast with our findings that securing loans increases repayment primarily by a reduction in moral hazard. This difference is likely attributable the contrast between digital and traditional collateral and to differences in study design. In Jack et al. (2019), all loans were secured—borrowers in default faced physical repossession regardless of the treatment group. Whereas, in our study, borrowers faced digital repossession when they were delinquent and not just in default, but only if they were assigned to the secured treatment group.

**Microfinance** The effectiveness of microcredit as a tool to combat poverty appears to be more modest than advocated by its early proponents and unlikely to be a major pathway out of poverty for much of the population (Banerjee et al., 2015; Meager, 2019). Moreover, microfinance institutions (MFIs) are struggling as the costs of making small loans to poor clients are high, in part due to mediocre repayment (Cull et al., 2018). We demonstrate that securing loans with digital collateral can significantly reduce lending costs and remain both attractive and seemingly beneficial to households.

MFIs turned to joint liability lending as a means to address repayment issues. Under joint liability small groups of borrowers are responsible for the repayment of each other’s loans. All group members are treated as being in default when at least one of them does not repay and all members are denied subsequent loans. Because co-borrowers act as guarantors they screen and monitor each other and in so doing reduce agency problems between the MFI and its borrowers (Ghatak and Guinnane, 1999). Theory suggests that joint liability may reduce adverse selection (Ghatak, 1999, 2000; Gangopadhyay et al., 2005) and moral hazard (Stiglitz, 1990; Banerjee et al., 1994; Laffont and Rey, 2003; Besley and Coate, 1995; Bhole and Ogden, 2010).

However, the empirical evidence on the effectiveness of joint liability is mixed. Attanasio et al. (2015) find no differences in repayment rates between joint and individual liability from
a field experiment in rural Mongolia. Gine and Karlan (2014) examine the impact of joint liability on repayment through two experiments in the Philippines. They find that joint liability did not affect repayment rates over the ensuing three years. Carpena et al. (2012) exploit a natural experiment in which an MFI in India switched from individual to joint liability and find that joint liability significantly improved repayment.

The downsides to joint-liability lending are that it often involves frequent and time-consuming repayment meetings, making it potentially onerous for borrowers. In addition, it exerts strong social pressure and can suppress efficient risk taking (Giné et al., 2010). For these reasons, many MFIs (such as ASA, Grameen Bank II, and BancoSol) have started to move from joint liability to individual lending (Cull et al., 2009).

Education in Developing Countries Out-of-pocket costs are an important constraint to education in most African countries, as families are asked to pay for things like school fees, books, uniforms, meals, and transport (Williams et al., 2015). A number of recent observational studies find that reducing or eliminating those costs improve enrollment and educational attainment in African countries (İşcan et al., 2015; Moussa and Omoeva, 2020; Ajayi and Ross, 2020; Adu Boahen and Yamauchi, 2017; Masuda and Yamauchi, 2018; Chicoine, 2019, 2020; Delesalle, 2019; Valente, 2019; Moshoeshoe et al., 2019). In a randomized controlled trial, Duflo et al. (2019) show that scholarships for students in Ghana, who had already passed the entrance exam but lacked financing, increased both secondary and tertiary attainment as well as long-run labor market outcomes.

To our knowledge, our study is the first to demonstrate that loans are an effective mechanism for increasing K-12 enrollment and school-related expenditures in LMICs. However, for tertiary education, loans are common and have been studied in some middle income countries such as Chile, South Africa and China (Solis, 2017; Gurgand et al., 2011). While loans have been
effective in improving college enrollment, several studies have found evidence of adverse effects on students graduating with debt (Cai et al., 2019; Dearden, 2019). In contrast, our study does not suggest K-12 loans add undue burden to households’ balance sheets.

3 Model

In this section, we propose a stylized model of collateralized lending. Our primary contribution is to decompose the repossession technology into two independent parameters in order to isolate and understand the role of each. We use “lockout” to refer to the parameter that controls how much value the household loses in repossession and “recovery” to refer to how much value the firm recovers in repossession.

We start with two intuitive observations that help frame our experimental design. First, using lockout to secure a loan increases borrower’s repayment incentives thereby reducing the moral hazard problem; more effective lockout implies less moral hazard. Second, when combined with a downpayment, lockout leads to positive selection: borrowers with sufficiently high (ex-ante) income risk will be unwilling to take a loan secured with digital collateral. In combination, these findings imply that the lockout technology makes it easier for firms to recover production costs and increases the supply of credit. Perhaps less intuitive is that we also find a stronger lockout technology leads to less strategic default and less repossession in equilibrium, which is precisely the opposite of the effect of a higher recovery value (Proposition 3). Moreover, we illustrate by example that a stronger lockout technology does not necessarily increase welfare, which can explain the lenient nature in which it is deployed in practice.

The model has two dates (0 and 1) and two types of agents (households and firms). Households would like to purchase a durable good produced by firms, but have limited wealth. Firms produce the good and can also provide financing for it. However, due to incomplete markets (e.g.,
moral hazard, adverse selection), firms require collateral in order to underwrite household debt.

**Households.** There is a unit mass of households, indexed by \( i \in [0,1] \). Household \( i \) derives utility from consuming the production good at date 1, denoted by \( \tilde{v}_i \), which is distributed according to \( F \) on support \([\underline{v}, \bar{v}] \subseteq \mathbb{R}\). Household \( i \) privately observes \( \tilde{v}_i \) at the beginning of date 1.\(^{10}\)

Each household has date-1 income denoted by \( \tilde{y}_i \). Households are heterogeneous with respect to income risk. With probability \( q_i \), household \( i \) experiences an income shock and \( \tilde{y}_i = 0 \). With the complementary probability, household \( i \) has sufficient income, \( \tilde{y}_i = y > \bar{v} \), but may still choose to strategically default. Thus, higher \( q_i \) correspond to riskier households. Without loss of generality, assume that \( q_i \) is increasing in \( i \). Households know their risk type. Let \( G \) and \( g \) denote the distribution and density of risk types in the population, which has support \([0,1]\). For simplicity, we assume that all households have the same wealth \( w_i = w \) for all \( i \) and that households are risk-neutral utility maximizers with a discount factor normalized to 1.\(^{11}\)

**Firms.** There are \( N \geq 1 \) identical firms. Each firm has the technology to produce a good that generates value for households at date 1. Each firm has a marginal production cost \( c \). Firms also have the ability to provide financing to their customers. More specifically, firms offer a contract, which is a pair \((d,p)\), where \( d \) is the downpayment required at date 0 to take possession of the good and \( p \) is the price of consuming the good at date 1. If a household takes possession at date 0, but does not make the payment at date 1, then the firm “repossesses” the good.\(^{12}\)

\(^{10}\)A higher realization of \( \tilde{v}_i \) can be interpreted either as a shock leading to a particularly high value for consuming the good or from a positive income shock and thus a lower marginal utility from consumption of other goods.

\(^{11}\)Risk-neutrality simplifies the space of relevant contracts since there is no demand for intra- nor inter-temporal consumption smoothing.

\(^{12}\)We take the form of contract as given because it is representative of what is used in practice by PAYGO lenders and in our experiment. If households are identical ex-ante (e.g., \( q_i = q \) for all \( i \)) then this contract is optimal within a more general class of mechanisms in which the date-1 transfer and repossession are contingent on the household’s reported value.
Repossession. Should the borrower fail to repay, repossession has two implications. First, the lender recovers something of value. Second, the household loses something of value, which provides incentives to repay the loan conditional or decline the loan offer.

In most models of collateralized lending, these two roles, recovery and incentives, are inseparable and characterized by a single parameter (e.g., Kiyotaki and Moore 1997). The lockout technology facilitates a decoupling of the two roles by providing incentives without the cost and benefits associated with physical repossession. To separate the two roles, we parameterize firms’ repossession technology by the pair \((\kappa, \lambda)\), where \(\kappa\) denotes the effectiveness of recovery—it is the fraction of the production cost that the firm recovers from repossession, and \(\lambda\) denotes the effectiveness of repossession on incentives—the borrower enjoys only a fraction \(1 - \lambda\) of her value for good when it is repossessed.

As discussed earlier, physical repossession is costly in economies with weak creditor rights and limited enforcement. Therefore, a (traditional) collateralized loan, where the asset is physically repossessed in default, is characterized by relatively low \(\kappa\). A loan secured with digital collateral may involve little recovery in default (i.e., \(\kappa = 0\)), but still provide strong incentives for borrowers (i.e., \(\lambda > 0\)). Our primary interest will be to explore how an an increase in \(\lambda\) (i.e., a more effective lockout technology) affects equilibrium quantities.

We make the following parametric assumptions.

**Assumption 1** (Trade is efficient ex-ante). \(E[\tilde{v}_i] > c\).

**Assumption 2** (Repossession is inefficient ex-post). \(\lambda v > \kappa c\) for all \(v \in [\underline{v}, \bar{v}]\).

Given these assumptions, the first-best outcome is for all households to purchase the good and for firms to never repossess the good. This outcome can be sustained as an equilibrium even without lockout if households have sufficient wealth. Assumption 3 rules out this possibility.

\(^{13}\)One can interpret \(\lambda\) as the probability with which the good is successfully repossessed from the borrower and \((1 - \kappa)/\lambda\) as the rate of depreciation or the cost of repossession the good (as a fraction of \(c\)).
Assumption 3 (Households are financially constrained). $w < c - v$, but households that do not experience a shock have sufficient wealth and income to afford the good: $w + y > c$.

Finally, we impose the Myerson (1981) regularity assumption on the distribution of values.

Assumption 4 (Monotone virtual surplus). $v - \frac{1 - F(v)}{f(v)}$ is monotonically increasing in $v$.

This assumption holds for many commonly used distributions (e.g., uniform, normal, exponential), is implied by the monotone likelihood ratio property (MLRP), and is often employed in mechanism design.

3.1 Household Behavior

We begin by considering the behavior of households taking the contract $(d, p)$ as given. Suppose that household $i$ purchases the good at date 0. The household will repay at date 1 provided that (i) it does not experience an income shock, and (ii) that its utility for consuming the good is sufficiently high:

$$\tilde{v}_i \geq \frac{p}{\lambda}. \quad (1)$$

Our first observation is that a more effective lockout technology leads to a higher probability of repayment.

Proposition 1 (Lockout Reduces Moral Hazard). Fixing a contract, a more effective lockout technology (i.e., higher $\lambda$) decreases the probability that household $i$ strategically defaults.

Consider now the purchase decision of households. The expected date-1 surplus to household $i$ is given by

$$S_i(p) \equiv (1 - q_i) \left[ \int p \max \{v - p, (1 - \lambda)v\} dF(v) + q_i (1 - \lambda) E(\tilde{v}_i) \right].$$
Household $i$ will purchase the good if they can afford to do so and the surplus from purchasing is non-negative. More concisely, household $i$ will purchase the good if

$$d \leq \min\{w, S_i(p)\}.$$  

(2)

Let $U_i(d,p) = S_i(p) - d$ denote household $i$’s expected utility from purchasing the good. Noting that $S_i(p)$ is decreasing in both $q_i$ and $\lambda$, we have the following result.

**Proposition 2 (Lockout Reduces Adverse Selection).** Fix a contract $(d,p)$ such that $S_1(p) < d \leq w < S_0(p)$. Then, there exists $q \in (0,1)$ such that only households with income risk $q_i \leq q$ accept the contract. Moreover, $q$ is decreasing in $\lambda$.

This result shows that in combination with a downpayment, lockout leads to positive selection. Households with more credit risk prefer not to make a downpayment for the good because they anticipate a higher chance of being locked out. It is worth noting that Proposition 2 is only a partial equilibrium result. In equilibrium, the firm will respond to a change in $\lambda$ by adjusting the contract. The first statement of the proposition continues to hold in equilibrium (Corollary 1). However, the comparative static of $\lambda$ on $q$ is ambiguous.

### 3.2 Firm Profits

The lowest utility type that strategically defaults when the price is $p$ is

$$v(p) = \begin{cases} v & p \leq \lambda v \\ p/\lambda & p \in (\lambda v, \lambda \bar{v}) \\ \bar{v} & p \geq \lambda \bar{v}. \end{cases}$$  

(3)

\footnote{Figure 1 illustrates that $q$ increases when $\lambda$ goes from 0.6 to 0.8, but decreases when $\lambda$ goes from 0.8 to 1.}
For any $p$, the probability that household $i$ repays is $(1 - q_i)[1 - F(v(p))]$ and a firm’s expected revenue at date-1 from selling to household $i$ is

$$R_i(p) = \kappa c + (1 - q_i)[1 - F(v(p))](p - \kappa c).$$

Date-1 revenue is increasing in both $\kappa$ and $\lambda$ and decreasing in $q_i$. The profit from selling to household $i$ is

$$\pi_i(d,p) = \begin{cases} 
  d + R_i(p) - c & \text{if } d \leq \min\{w, S_i(p)\} \\
  0 & \text{otherwise.}
\end{cases} \quad (4)$$

### 3.3 Equilibrium

The equilibrium will naturally depend both on the degree of competition among firms. Here, we consider the monopolistic equilibrium with observable household risk. In the appendix, we demonstrate the results are robust with respect to this specification.

When the firm is a monopolist, the contract offered to household $i$ solves

$$(d_i, p_i) \in \arg\max_{d, p} \pi_i(d,p)$$

We decompose the problem into two steps. First, maximize profit conditional on selling to household $i$. Then decide whether to sell to household $i$. Clearly, the firm’s profit is increasing in $d$. So it will be optimal to set $d_i = \min\{w, S_i(p)\}$. Thus, the firm’s problem can be written as

$$\max_p (\min\{w, S_i(p)\} + R_i(p) - c)$$

Consider the problem of maximizing date-1 revenue with respect to the lowest type that
strategically defaults, \( v = p/\lambda \). The marginal revenue from increasing \( v \) is

\[
(1-q_i)[(1-F(v))\lambda - f(v)(\lambda v - \kappa c)].
\]

and the first order condition is

\[
v^* - \frac{1-F(v^*)}{f(v^*)} = \frac{\kappa c}{\lambda},
\]

which has a unique solution by Assumption 4. Notice that \( v^* \) is independent of \( q_i \), and increases with \( \kappa \), but decreases with \( \lambda \). Both higher \( \kappa \) or higher \( \lambda \) correspond to a “better” repossession technology, but they have different effects on the marginal household type who strategically defaults; higher \( \kappa \) gives the firm more incentive to repossess which increases \( v^* \), whereas higher \( \lambda \) decreases \( v^* \).

Equation (5) is intimately linked to the monopoly price. In particular, when households’ are sufficiently constrained, the monopoly price is \( p^* \equiv \lambda v^* \).

**Lemma 1 (Monopoly Prices).** **Conditional on selling to household** \( i \), the solution to the monopolist problem involves \( d_i = w \) and

\[
p_i = \begin{cases} 
  p^* & \text{if } w \leq S_i(p^*) \\
  S_i^{-1}(w) & \text{otherwise}
\end{cases}
\]

When household wealth is small, the monopolist prioritizes date-1 revenue by charging \( p_i = p^* \). When \( w > S_i(p^*) \), the firm charges less than \( p^* \) at date 1 in order to extract a larger downpayment. Focusing on the first case, we have the following contrast between the two roles of repossession.

**Proposition 3 (Recovery vs Lockout).** **When the firm is a monopolist and household wealth is sufficiently small, i.e.,** \( w < S_i(p^*) \):

- More efficient recovery (higher \( \kappa \)) leads to more strategic default and repossession.
• **More effective lockout (higher \( \lambda \)) leads to less strategic default and less repossession.**

Increasing \( \kappa \) gives the firm more incentive to repossess the good and makes strategic default less of a concern. So the firm sets a higher price and households default more frequently. The first part of Proposition 3 is consistent with empirical evidence from a natural experiment [Assunção et al. 2013]: making it easier for lenders to recover value from collateral leads to an increase in credit supply but also higher default rates. While increasing \( \lambda \) also expands credit supply, it has the opposite effect on default rates. It makes strategic default more costly to the firm because it increases the wedge between the firm’s payoff conditional on repayment and the payoff conditional on default.

If the implied profit from the contract in Lemma 1 is positive, then it is optimal for the firm to sell to household \( i \). Otherwise, the household will reject any offer that the firm is willing to make.

**Proposition 4 (Monopoly Quantities).** The firm will sell to household \( i \) if and only if either

(i) \( w + R_i(p^*) \geq c \) when \( S_i(p^*) \geq w \), or

(ii) \( w + R_i(S_i^{-1}(w)) \geq c \) otherwise.

Noting that both \( R_i \) and \( S_i \) are decreasing in \( q_i \), we can conclude that positive selection also emerges as an equilibrium outcome.

**Corollary 1.** For any \( \lambda > 0 \), there exists \( q^* \) such that only households with \( q_i < q^* \) will purchase the good.

Since the downpayment is simply a transfer, we can ignore it when computing total surplus, which is given by

\[
TS = \int_0^{q^*} (R_i(p_i) + S_i(p_i) - c)dG(q_i).
\]

Total firm profit and consumer surplus are given by \( \Pi = \int_0^{q^*} \pi_i(d_i, p_i)dG(q_i) \) and \( CS = \int_0^{q^*} U_i(d_i, p_i)dG(q_i) \).
Figure 1: Equilibrium prices with a monopolist firm. All households who purchase the good face a downpayment equal to their initial wealth: (i.e., $d_i = w$).

**Parametric Example** Suppose that both $\tilde{v}_i$ and $q_i$ are uniformly distributed on [0,1]. Let $\kappa = 0$ and $c = \frac{1}{4}$, and let $w$ and $\lambda$ be free parameters. Then $v^* = \frac{1}{2}$, $p^* = \frac{3}{2}$, and

$$R_i(p^*) = \frac{1}{4}\lambda(1-q_i),$$

$$S_i(p^*) = \frac{1}{2} - \frac{\lambda(3+q_i)}{8}.$$ 

There are two possible cases depending on $\lambda$ relative to $c - w$.

(i) For $\lambda < 4(c - w)$, then $q^* = 0$ meaning that no households purchase.

(ii) For $\lambda \geq 4(c - w)$, $q^* = 1 - \frac{4(c - w)}{\lambda}$ and the mass of households that purchase is

$$G(q^*) = 1 - \frac{4(c - w)}{\lambda}.$$ 

Figure 1 illustrates the solution to the monopolist’s problem as it depends on both household risk type as well as $\lambda$. For $\lambda = 0.6$, the firm sells only to households with $q_i \leq 0.45$ and all household who purchase the good get the same price $p^*$. For $\lambda = 0.8$, the firm sells to more households and (mostly) at higher prices; households with $q_i < 0.33$ face a price of $p^*$, those with intermediate income risk ($q_i \in (0.33, 0.58)$) are unwilling to purchase at $p^*$, but are still profitable
so the firm sells to them at $S_i^{-1}(w)$. For $\lambda = 1$, even more households are profitable under the contract $(w,p^*)$, but none of them are willing to purchase at those terms. Therefore, the firm has to charge a price less than $p^*$ to all customers in order to induce them to purchase. As a result, the profitability of each customers falls and fewer households end up being served (i.e., $q^*$ falls).

Figure 2: Illustrating the role of lockout.

Quantity and profit is increasing in $\lambda$ as illustrated in the top panels of Figure 2. Household welfare increases with $\lambda$ on the extensive margin ($q_i = q^*$) as more households get served. However, households that were already purchasing the good ($q_i < q^*$) face higher date-1 prices. As a result, aggregate household welfare can decrease with $\lambda$. This possibility is clearly illustrated in Figure 2(b), where both household and total surplus decreases for $\lambda$ large enough. Intuitively, a stronger lockout technology increases the incentive to repay, but also destroys more value when the household defaults. This effect is most pronounced on households with higher income risk as they are more likely to default for non-strategic reasons.

That consumer surplus and total surplus may decrease with $\lambda$ can also obtain when firms are perfectly competitive (see Figure A.3(b)). These findings suggest that a more lenient
repossession policy may be preferable. For example, the firm could reposess the good only after a certain number of missed payments or only with some probability less than one. Indeed, a key innovation of the PAYGO model is that the punishment for missing a payment is not too severe. Failure to make a payment results in a punishment that is proportional to the flow value of consuming the good rather than the stock value (i.e., physical repossession).

3.4 Reusing digital collateral

The households in our experiment have already purchased the good and completed payments on the loan. The product that they are offered is a follow-up loan for school fees in which some fraction of the households are required to (re)-pledge the SHS as collateral in order to be eligible for the loan. It is straightforward to extend most of the results above to this setting. Increasing $\lambda$ reduces both moral hazard and adverse selection. Yet, higher $\lambda$ destroys more surplus after negative income shocks and therefore may reduce overall welfare.

Unlike the model above, a downpayment on a follow-up loan is not necessary to get positive selection—repledging collateral serves the role of the downpayment. Nevertheless, a feature of the loan product offered in our experiment is that it requires households to make a cash deposit (several days in advance) when the loan funds are disbursed, which can serve as an additional screening device.\footnote{To illustrate this claim, consider a three-date model, in which the household receives some income at date 0, has an investment opportunity at date 1, and receives additional income at date 2. The household owns a good that delivers value $\tilde{v}$ at date 2 and can be pledged as collateral for a loan at date 1. The firm offers a contact $(d,L,p)$, where $d$ is the downpayment at date 0, $L$ is the amount of the loan at date 1, and $p$ is the price the household must pay at date 2 in order to avoid repossession. If income is persistent then being able to make the downpayment at date 0 is a positive signal about the household’s ability to repay the loan at date 2 and serves as an additional screening device above and beyond household’s willingness to pledge their collateral at date 1.}
4 Experimental Setting

We test the effect of digital collateral on a school-fee loan product offered by Fenix International, a technology company operating in Eastern Africa. As of mid-2019, Fenix had more than half a million solar home system (SHS) customers across 6 countries in Sub-Saharan Africa. They are the largest SHS provider in Uganda. Fenix’s most popular system is 10 Watts and is able to power LED lamps and a radio, and charge cell phones. Fenix’s SHSs differ in several ways from the solar panels on homes in the US and Western Europe. First, they produce roughly two orders of magnitude less electricity than the typical solar panel installation on a US or Western European home. Second, they are standalone systems, meaning they are not connected to a grid.

Like most SHS providers, Fenix sells most of its units through a PAYGO model. Customers make a small down payment, less than $10, to take possession of the SHS. Subsequently, customers make small payments using mobile money until they have paid off the loan. If a customer does not make a payment on time, the SHS will lock (i.e., the battery will not discharge electricity) until the next payment is made.

Fenix also uses the remote payment and locking technology to offer product upgrades and secondary loans. Their most popular follow-up product is a school-fee loan. These are cash loans offered to the better-paying customers three times a year at the beginning of school terms.

Our study focused on a 300,000 Ugandan Shilling (UGX, $81) school-fee loan. Obtaining

---

16 See https://www.fenixintl.com/blog/ (Date accessed: October 29, 2020).
18 Fenix’s biggest system is 34 Watts and can support a variety of small electrical appliances including a fan, speakers, and a custom built 18.5-inch television. Information about Fenix’s system can be found https://www.fenixintl.com/product/ (Date accessed: October 29, 2020).
19 Over 85% of solar home systems sold in the second half of 2018 were sold on PAYGO (see Global Off-Grid Solar Market Report: Semi-Annual Sales and Impact Data, 2018. Available at https://www.gogla.org/publications).
20 All conversions from UGX to USD in this paper are at the 2019 average of 3,704 UGX to 1 USD. Source: https://data.worldbank.org/indicator/PA.NUS.FCRF?locations=UG.
the loan requires customers make a deposit of 20% (60,000 UGX, or $16). Several days after
making the deposit, the funds are disbursed to the customer via mobile money. Customers
receive seven free days of light after which they are responsible for making daily payments
of 3,000 UGX (less than $1) for 100 days. Most customers choose to pay for several days
or a week of light at a time rather than make daily payments. Fenix considers the loan to
be paid off as long as the customer makes nominal payments totaling $81 (not including the
deposit) within 145 days of the loan issue date. This arrangement implies that customers who
take longer to repay face a lower effective interest rate. For instance, a customer who makes
a payment every day pays an annual percentage rate (APR) of 168%, whereas a customer who
makes a payment only two out of every three days pays an APR of only 112%. Of course, the
latter APR does not reflect the cost of losing access to the SHS on locked days.

Customers who do not pay off the loan within 45 days of the target repayment date face
interest charges of 2% per month on any remaining principal. In addition, failure to repay the
loan in a timely manner renders customers ineligible for futures loan offers. After 180 days
of no payments, the loan is considered to be in default and Fenix reserves the right to repossess
the SHS system. In practice, only a very small fraction of defaults (less than 5%) result in
physical repossession, which is consistent with our hypothesis that the traditional repossession
technology is expensive and ineffective in this setting.

4.1 Background: Education and School Fees in Uganda

Formal schooling in Uganda starts at age 5. Primary school extends for seven years, through
age 12. Secondary school is for children aged 13-20. Primary and secondary-aged children in
Uganda have access to both government and privately run schools. In 2016, the most recent

\footnote{While down payments on collateralized loans are standard, a deposit in advance of a cash loan is an uncommon practice. We explore the implications of this practice in Gertler et al. (2021).}
year for which data are available, 80% of primary-aged students attended government-run schools and 20% attended privately run schools. At the secondary level, over 50% of children attend private schools. The government has offered a universal primary education program since 1997, although in practice not all students have access to subsidized primary education, and even those that do incur expenses for uniforms, books, school lunches and other supplies.

School fees and school related expenditures constitute a non-trivial portion of household expenses in Uganda. Conditional on enrollment, the median household spends 14% of income on primary education and 21% of income on secondary education based on data from the 2019 nationally representative Living Standards Measurement Study (LSMS). School fees for both government and public schools are typically due three times per year. Two of the three due dates are not proximate to harvest season, and hence are periods of low income across rural Uganda. In one study, 53% of families reported having their children sent home because they were unable to pay school fees (Intermedia, 2016).

5 Experimental Design

Figure 3 illustrates our experimental design. Our universe of eligible loan recipients consisted of Fenix customers that repaid the initial loan on their solar home system and did not have an outstanding school-fee loan. In May 2019 we sent an SMS message to the 27,081 eligible customers inviting them to reply if they were interested in a school-fee loan. 3,300 customers (12%) responded affirmatively. Table A.1 columns 1 and 2 uses administrative data to compare our sample of Fenix customers to population-wide statistics from rural Uganda based on the 2019 World Bank LSMS. Fenix customers are more likely to be male and married and have more children than the typical rural Ugandan head of household. They also are more likely to be employed outside

the agricultural sector and more likely to come from the (relatively more wealthy) central region.

We randomly allocated the interested customers into four groups - a control group, a treatment group that was required to post their SHS as (digital) collateral to get the loan (“Secured”), a treatment group that did not have to post collateral (“Unsecured”), and a treatment group that were offered the same terms as the Secured treatment group, but were later (positively) “surprised” that they would not have to post collateral after accepting the loan offer (“Surprise Unsecured”).

Following [Karlan and Zinman (2009)], this surprise allows us to separately identify moral hazard and adverse selection. More specifically, we identify the moral hazard effect by comparing repayment of the Secured group to the Surprise Unsecured group—both received and accepted the secured loan offer, but only the Secured group faced digital repossession for non-repayment. We identify the adverse selection effect by comparing the Unsecured group to the Surprise Unsecured group—neither group was ultimately required to post collateral, but the latter group accepted the loan expecting that they would have to post collateral and thereby were positively selected compared to the former.

Our call center attempted to reach the households in each treatment group using the phone number to which we had sent the SMS messages. The call center reached over 80% of households in the treatment groups. The call center explained that the customers were eligible for a loan and asked if they were interested in proceeding. The Secured and Surprise Unsecured treatment groups were informed they would have to post their SHS as (digital) collateral to obtain the loan, whereas the Unsecured treatment group was informed they would not have to post collateral.

Field teams administered a baseline survey to the set of customers that were offered a loan and the control group. In some cases, the field team reached households in the Surprise

\[23^{23}\] Originally, we considered including another arm where the loan was secured with physical collateral. However, the existing school-fee loan contract already has a provision for physical repossession. Fenix rarely executes this provision because it is costly and ineffective.
Unsecured treatment group and revealed the surprise before the household had made the deposit to finalize the loan. Thus, we observed a multi-stage decision process, in which households first verbally accepted the loan terms, but then only about half of those customers made the deposit. Given that some of the households in the surprise group knew they would not have to post collateral before they made the second decision (to pay the deposit), we separately considered only households that paid the deposit prior to interaction with the field team as a robustness check.

All households who received a loan were sent regular SMS payment reminders: on the payment due date, if they were two days late, and again if they were one week late in making a payment. This is standard practice for Fenix and is useful to rule out alternative hypothesis as we discuss in Section 7. We also conducted an endline survey six months after the loans had been disbursed.

6 Experimental Results

We delineate our experimental results into three categories: (i) take-up rates, (ii) repayment and profitability, and (iii) educational and balance sheet outcomes.

6.1 Take-up Rates

Take-up rates were high across all treatment groups. The bottom row of Figure 3 indicates the share of households in each group that took the loan as a share of households that the call center was able to reach. Consistent with our model, we see a clear indication that requiring households to post digital collateral serves as a screening device: 45% of households take the secured loan compared to 51% who take the unsecured loan. The take-up differential is statistically different from zero ($p = 0.004$).

Table A.4 in the Appendix explores whether there are significant differences in the baseline
characteristics of the households that took up the loan across treatment groups. Most baseline characteristics are statistically indistinguishable across the two groups, suggesting that digital collateral is screening on characteristics that are not captured by variables in administrative or survey data.

6.2 Repayment and Profitability

Repayment We measure repayment as the household’s cumulative payments towards the principal divided by the total loan principal (i.e., the fraction of principal repaid). Figure 4(a) plots the fraction of principal repaid over time for customers in the three treatment groups. Figure 4(b) plots the differences between the three groups.

Consistent with our model’s predictions, repayment in the Secured group is consistently higher than repayment in either Unsecured group. Overall, digital collateral increased repayment by 13 pp at both 100 days (from 46% to 59%) and 150 days (57% to 70%). As discussed in Section 5, the moral hazard effect is derived by comparing repayment in the Secured group to repayment in the Surprise Unsecured group. Moral hazard accounts for the bulk of the overall effect: 9 pp at both 100 and 150 days. The effect on adverse selection is derived by comparing repayment in the Surprise group to the Unsecured group; this accounts for 4-5 pp of the overall increase in repayment.

Table 1, Panel A presents results from regression specifications of the following form:

\[ r_{it} = \alpha_t + \beta_t \times Treatment \, group_i + \epsilon_{it}, \]  

(6)

where \( r_{it} \) is the repayment rate for household \( i \), \( t \) days after loan origination. The treatment effect is \( \beta_t \), \( \alpha_t \) is a constant, and \( \epsilon_{it} \) is an error term. The results in Table 1 reflect Local

\(^{24}\)Fenix credits commissions to customers who refer other customers to Fenix, and we include payments from these commissions, although they account for 0.2% of total payments towards principal.
Average Treatment Effects (LATE) estimates, accounting for imperfect compliance (i.e., the fact that some customers who were supposed to be locked were unlocked for some days and vice versa).

The column labeled “Lockout” captures the total effect of securing loans with digital collateral. The specification in this column includes households in the Secured and Unsecured groups, where Treatment group \(i\) is equal to one for households in the Secured group. The specification in the column labeled “Adverse Selection” includes households in the Surprise and Unsecured groups, where Treatment group \(i\) is equal to one for households in the Surprise group. The specification in the column labeled “Moral Hazard” include households in the Secured and Surprise groups, where Treatment group \(i\) is equal to one for households in the Secured group. The rows report the results at \(t = 100, 150\) and \(200\) from loan origination. The last column provides the p-values for the hypothesis test that the moral hazard effect is equal to the adverse selection effect. The standard errors indicate that the overall lockout effect is significant at the 1% level, the moral hazard effect significant at the 5% level while the adverse selection effect is not statistically significant.

As an alternative measure of repayment, we consider the fraction of loans that have completed payments in Table 1, Panel B. A loan is recorded as completed when the repayment rate equals one. Our results convey a similar message under this alternative measure. Lockout leads to a 19 pp increase in the completion rate after 200 days, with moral hazard accounting for slightly more than two thirds of the total effect and adverse selection accounting for slightly less than one third of the total effect.

---

25 Altogether, fewer than 10% of the loan days were not in compliance. There were two general types of imperfect compliance: (1) administrative errors at the beginning of the experiment, and (2) customers who had additional transactions with Fenix over the study period, for example to upgrade their solar home system, and were sometimes switched to the wrong locking arrangement. See Appendix A Tables A.5 and A.6 for more details and for the Intent to Treat (ITT) estimates of the specifications reported in Table 1, respectively.
**Profitability**  To understand how customer repayment translates to firm profitability, we calculate the monthly internal rate of return (IRR) on loan portfolios. Table 2 summarizes the results and shows that using digital collateral increased the monthly IRR by 3.2 pp (38 pp annualized). When we restrict attention to loans with perfect compliance (Table A.8), the increase in profitability is even larger 4.5 pp (54 pp annualized). We sorted households into terciles based on their repayment history prior to taking the school-fee loan (i.e., account percent locked). Loans in each tercile are formed into a portfolio. The first tercile corresponds to households with the highest repayment rates prior to taking the school-fee loan. Table 2 illustrates that digital collateral increased profitability by more for the first two terciles (3.9 pp and 3.8 pp, respectively) than it did for the third tercile (1.8 pp).

It is noteworthy that all of the unsecured loan terciles have a negative IRR and only the first tercile of secured loans has a positive IRR. There are several takeaways from this finding. First, the unsecured lending contract is not profitable even among households who have previously been good repayers. Second, securing a loan with digital collateral does not ensure profitability. Screening remains a necessary component of a sustainable lending business. For the purposes of this study, we expanded Fenix’s eligibility criterion and increased the loan size. Under Fenix’s usual business practices, (i) all school-fee loans are secured, (ii) only households with above median repayment history (among our sample of loans) would be eligible for a school-fee loan, and (iii) as first-time borrowers, they would only be eligible for a loan one-third of the size. Thus, our findings are consistent with Fenix’s usual business practices being value maximizing.

---

26 The internal rate of return is the discount rate such that the net present value of cash flows on the portfolio is equal to zero.

27 Account percent locked is the percentage of days in which the household’s SHS was locked due to non-repayment of loans prior to taking the school-fee loan. While all had completed payments on the original SHS loan, some took longer to do so and thereby were locked a higher percentage of days.

28 Our study offered 300,000 UGX ($81) loans to customers who had never had a school-fee loan, while the prior school-fee loans were smaller (100,000 UGX, $27) for first-time borrowers. Fenix offers larger loan sizes to customers after they have successfully paid off their first school-fee loan.
For more perspective on profitability, we calculated IRRs for school-fee loans that Fenix had offered in prior school terms (in 2018) under their usual business practices, again broken into terciles based on repayment history. As illustrated by the bottom row of Table 2, the prior school-fee loans have significantly better repayment history and are considerably more profitable. The monthly IRR is 6.6%, 6.0%, and 3.2% across the three terciles with an average monthly IRR of 5.1%.

**Heterogeneity across households**  
Table 4 analyzes the treatment impact on repayment rates and loan completion for households that were above and below median number of days locked on the original SHS loan. This allows us to assess the extent to which households with higher a priori risk had lower repayment and loan completion rates because of selection or moral hazard. The coefficients on the interaction term in Table 4 suggest that digital collateral increased repayments and completion slightly more for higher risk households. Interestingly, virtually all of the increase in repayment for higher risk households is due to moral hazard and not selection, whereas the opposite is true for lower risk households.

Second, we analyze heterogeneity in willingness to pay (WTP) for the electricity provided by the SHS. If we incorporated this heterogeneity into our model, it would predict that households with a higher WTP would be less willing to accept a locked loan compared to lower WTP households. Figure 5 analyzes loan take-up by respondent’s stated WTP for a extra day of access to their SHS. We group the responses into three categories (low, medium, and high). Indeed, households with the highest WTP are significantly less likely to accept a secured loan compared to an unsecured loan, while households in the low and medium groups are equally likely to accept them. Also consistent with our model, we found the effect on repayment is

---

29 Until recently, Fenix’s systems did not record the number of hours of use by households, so we could not use that as a revealed preference measure of value, although even average hours of usage would be an imperfect measure.
larger for households with above median WTP for solar (see Table A.14). For instance, the effect of securing with digital collateral is 10 pp higher at 150 days for households with above (vs below) median willingness to pay.

We also test robustness of our main estimates by exploring heterogeneity with respect to how quickly households accepted the loan. As mentioned in Section 5, after accepting the loan, some of the households in the Surprise Unsecured group were notified by our field staff that they would not be required to post collateral before completing the paperwork and making the deposit. It is possible that the households who made the deposit after they were notified were different than the households in the Secured treatment group. To understand by how much this potential selection affects our decomposition results, we re-estimated versions of the specifications in Table 1 using only those households that completed the deposit before they were visited by our field staff. These results are reported in Table A.7. Interestingly, the overall effect of digital collateral on repayment is almost two times as large among this set of people, pointing to considerable heterogeneity. Nevertheless, the overall conclusion that moral hazard explains the bulk of the effect remains.

### 6.3 Schooling Outcomes

While the results presented thus far clearly suggest that securing loans with digital collateral increases repayment and firm profitability, we are also interested in the impact of the loans on household-level outcomes. At a high level, access to credit may facilitate welfare-enhancing investments in human capital. As discussed in Section 4, the loans we study were offered in May 2019, just before school fees were due for Term 2. The product was marketed as a school-fee loan, though Fenix offered them to all eligible customers, regardless of whether they had school-aged

---

30Note that this potential selection does not impact the estimate of the overall effect.
Nevertheless, almost 90% of our sample households had school-aged children and 92% who accepted a school-fee loan reported using it for education-related expenditures.

To understand whether the loans had an impact on schooling outcomes, we estimate the following equations:

\[ y_i = \alpha + \beta \times \text{Loan Offer}_i + \epsilon_i \]  
\[ y_i = \alpha + \beta \times \widehat{\text{Loan}}_i + \epsilon_i, \]  
where \( y_i \) is an outcome variable for household \( i \). Equation (7) yields the intent to treat (ITT) estimates, where \( \text{Loan Offer}_i \) is an indicator for a household that was offered a loan through one of the three (locked, surprise unlocked, unlocked) groups. Equation (8), estimated by instrumenting for \( \text{Loan}_i \) with \( \text{Loan Offer}_i \), yields the local average treatment effect (LATE) for households that accepted loans. In what follows, we focus on discussing the LATE estimates, and the ITT estimates are reported in the Appendix.

Table 5 reports results from estimates of equation (8) for several schooling-related outcomes. We report the LATE estimate separately for each treatment group and for the pooled sample of all households offered credit. Columns 1 and 2 report impacts on the share of 5 to 20-year-old children within a household who are enrolled in school. The sample is restricted to households that had at least one child in that age range at the endline survey. In the pooled sample, the loan increased school enrollment by 6 pp. Given that 88 percent of children in the control group are enrolled, access to the loan reduced the share of children who are not enrolled by roughly half.\(^{31}\) The increase in enrollment was largest in the Secured group (8 pp). The effect was smaller, but not statistically different, in the Unsecured group (5 pp) and the Surprise

\(^{31}\)Enrollment rates among households in our sample appear roughly comparable to enrollment rates for the population. According to the LSMS, nationwide 91% of primary school-aged children and 68% of secondary school-aged children are enrolled at school.
Unsecured treatment group (2 pp).

Columns 3 and 4 of Table 5 analyzes the impact on monthly absences from school for households that had at least one child enrolled. The coefficients are precisely estimated and suggest no meaningful impact on days absent. Column 6 shows that expenditures for school-related items (including school fees, uniforms, supplies, transport and meals) increased by 34.6% for households who received a loan (i.e., the Pooled sample). The increase in school-related expenditures corresponds to roughly 44% of the loan amount (net of the deposit) or $29.7. The increase in expenditures was largest in the Secured treatment group (42%) and smaller, but again not statistically different, in the other two treatment groups.

Table 6 presents the LATE results on enrollment and expenditures by child, separating outcomes for males and females. The unit of observation is now the child and not the household. We therefore cluster standard errors at the household level for statistical inference. This table indicates that the increased enrollment was concentrated among male children, who have a lower base rate (control mean) of enrollment, possibly because they were more likely to be working. The loan then may have not only been used to cover school costs but also used to offset lost income from reduced child labor supply. Among females, the effect on enrollment was not statistically significant. The loan was associated with a significant increase in school expenditures for both males (29 pp) and females (46 pp) by a similar magnitude to the household-level results.

In summary, Fenix’s loans had an economically meaningful and statistically significant impact on educational outcomes. The point estimates are largest for the Secured treatment group, but not statistically different from the other two treatment groups. These findings suggest that households did not have another source of liquidity to use for schooling-related expenditures. The LSMS reinforces this interpretation: only 3% of households in the LSMS

\[ e^{0.297} - 1 = 34.6\% .\]

\[32\] The estimated coefficient of the loan on log expenditures is 0.297. So, the percentage increase in expenditures for households who received a loan is \[e^{0.297} - 1 = 34.6\% .\]
had a loan with a commercial bank, only 6% had other formal loans, and only 1% had a loan with a microfinance institution.

6.4 Household Balance Sheet Outcomes

Loans with high interest rates, especially if they are misunderstood by customers, may have detrimental effects on households’ balance sheet. Table 7 reports the results of the estimation of equations (7) and (8) on household balance sheet outcomes, specifically purchases and sales of household assets and on borrowing in the six months prior to the endline survey. The estimated effects of the loan on changes in household balance sheets are small and not statistically significant for all 3 outcome variables. We repeated the analysis using endline stocks of assets, loans and net differences variables in Table 8. The estimated effect of the loan on household net balance is small and is not statistically different from zero.

The point estimates show that borrowing among the pooled treated groups is $52 higher than in the control group (Table 7), which corresponds to 77% of the loan amount (net of the deposit) and is commensurate with the estimated increase in school spending discussed in the previous section. This suggests that households in the treatment group did not have access to a substitute for the school-fee loan, although the differences in borrowing are not statistically significant.

For another perspective on the impact on a household’s financial position, we asked a series of questions about financial shocks that households had experienced in the six months prior to the survey and their concern about being able to cope with those shocks. The results are summarized in Table 9. Panel A reports the results for shocks including not having enough money for basic needs including (i) food and clothing, (ii) living expenses, (iii) education, (iv) medical treatment, and (v) debt owed to others. The dependent variable in columns (1) and (2) is the proportion of these five categories of shocks that household’s experienced in the last
6 months. For instance, in the control group, the typical household experiences two out of five of these shocks. Notably, we found no effect of having a loan on the propensity to experience these types of shocks. In columns (3) and (4), the dependent variables show how worried the household is about being able to cope with these shocks. Again, there is no impact of the loan on worrying about coping with the shocks. Panel B reports the results for shocks related to health, unemployment, accidents, and disasters. Again, we see no systematic or significant differences between households that were offered loans and the control group.

7 Discussion

In this section we discuss alternative explanations for our findings and other potential channels through which digital collateral may affect credit market outcomes. We conclude with a discussion of the welfare implications.

7.1 Alternative Explanations

We have interpreted digital collateral as providing a repayment incentive for households that reduces both moral hazard and adverse selection. An alternative interpretation is that getting locked simply serves as a reminder or a nudge to repay. Indeed, there is evidence that payment reminders increase on-time repayment (Cadena and Schoar 2011, Medina 2020). In our setting, this explanation is less plausible because all of the borrowers (secured or unsecured) received frequent payment reminders. Fenix sent reminders to all customers three days and one day before payment was due, on the day the payment was due, when the customer was two days late, and when the customer was one week late.

The estimated effect of digital collateral on reducing moral hazard is large and significant. Yet, it is possible that our estimate is biased downward for the following reason. Fenix offers
school-fee loans three times per year. In order to be eligible, the customer must have completed payments on their prior school-fee loan (i.e., completed the loan within 120 days). Thus, households with a high continuation value for a loan in the next term have a strong incentive to complete payments in a timely manner regardless of whether digital collateral is applied.\footnote{Within the context of the model from Section \ref{sec:assumptions}, if we consider a locked loan to have $\lambda=1$ and an unlocked loan to have $\lambda=0$, then $m = 1 - F(p)$ is simply the fraction of households with $v_i$ greater than the price.}

If the set of households with a high continuation value overlaps with the set of households that responds to the incentives from lockout, then our estimate is biased downward.\footnote{We are grateful to Antoinette Schoar for pointing out the potential for a downward bias.}

To get a sense for the magnitude of the bias, suppose a fraction $q$ of such households have a high continuation value and complete payments within 120 days regardless of whether or not lockout is applied. Absent this high continuation value, the true effect of lockout on increasing loan completion is $m$.\footnote{Consistent with this view, notice that Figure \ref{fig:completion}(c) exhibits a moderate increase in the rate of loan completion right near the 120 day for all treatment groups.} If continuation value and willingness to pay are independently distributed, then we would estimate the (moral hazard) effect on loan completion to be $(1 - q)m$. Under the assumption of independence, we can provide an upper bound on $m$ using the observation that 40\% of households in the surprise unlocked treatment complete the loan within 120 days. Thus, $q$ is at most 0.4 and $m$ is at most two thirds larger than the effect size that we estimate.

Our finding that adverse selection accounts for a smaller portion of the increase in repayment than does moral hazard can partially be attributed to the fact that our sample has already been screened via other measures. First, in order to be eligible for the school-fee loan, customers must have already successfully completed payments on the initial SHS loan. The adverse selection effect is likely to be larger on the initial loan. Second, eligible school-fee loan customers are required to put down a 20\% deposit before getting the school-fee loan. In an experiment on a different sample of Fenix customers, we investigated the role of the deposit and found evidence consistent with it serving as a screening device (Gertler et al., 2021).
7.2 Other Potential Roles for Digital Collateral

In addition to reducing moral hazard and adverse selection, there are other implications securing loans with digital collateral. First, the digitally secured loan contract effectively functions as a commitment-savings device. Much like a typical fully amortizing mortgage contract, each payment that a customer makes covers both interest and principal. The principal payment is akin to savings. This savings vehicle could be particularly valuable to households who lack self control because there is an added incentive to save \cite{Laibson1994}—to avoid temporary repossession and the savings are illiquid and cannot be easily or immediately accessed \cite{Laibson1997}.

Second, if lenders lack commitment power to physically repossess collateral, they may face a hold-up problem \cite{HartMoore1998} from strategic borrowers who know they will be tempted to renegotiate rather than incur repossession costs. By effectively lowering the lender’s repossession cost, the lockout technology provides a credible method to avoid the hold-up problem.

Finally, because repossessing digital collateral imposes a cost on borrowers without any reciprocal benefit to lenders, it may raise ethical questions especially if the primary reason for nonpayment is due to income shocks rather than strategic default. Are there financial contracts that are too punitive for borrowers? Should governments regulate certain contracts on ethical grounds?\footnote{An economic reason to regulate certain types of financial contracts is if the punishments impose externalities on third-parties \cite{BondNewman2009}.} These are important questions, and our study aims to provide evidence useful to inform answers. However, for the particular product in our experiment, we do not believe they should be of much concern. First, as discussed earlier, digital repossession in our setting is temporary and reversible, so it can be significantly less punitive than physical repossession, a practice that is widely accepted. Second, the magnitude of the cost imposed on households by digital repossession of their SHS is small compared to those that are usually restricted on moral grounds (e.g., imprisonment or bondage). Finally, the households in our study are familiar with the
contractual terms and appear to make informed decisions: households with a higher willingness to pay for the service flow from the SHS were significantly less likely to take-up secured loans.

7.3 Welfare Implications

There are several channels through which the introduction of digitally collateralized loans may affect welfare. This first is through an increase in credit supply. Our results suggest that firms should be unwilling to offer unsecured school-fee loans due to their low repayment and negative profitability. Observational evidence is consistent with this finding: unsecured credit for investment in education is not offered by for-profit firms in Sub-Saharan Africa. Therefore, the appropriate counterfactual household to investigate the welfare implications of the secured treatment group is the control group, who were not offered (digitally secured) school-fee loans.

By a revealed preference argument, the ex-ante expected welfare should be higher for households who were offered the opportunity to take a secured school-fee loan compared to the control group. Consistent with this argument, the secured treatment group exhibits an increase in school enrollment by 8 pp (Table 5, column (1)) and more investment in school-related expenditures by 42% (Table 5, column (5)) suggesting that the access to credit leads to a greater accumulation of human capital. In order to make this investment, the secured treatment group borrows $46 more than the control group (Table 7, column (5)). While this additional debt is not statistically significant and constitutes only a small percentage of household income (≈3%), it matches the reported increase in school expenditures and suggests that the control group did not have access to close substitutes.

Because this is a long-term investment and we do not find significant treatment effects on household balance sheet, we can infer household likely decreased current consumption moderately.

\footnote{The estimated coefficient of the secured treatment on log school expenditures is 0.35. So, the percentage increase in expenditures for the secured treatment group is $e^{0.35} - 1 = 42\%$.}
in order to make the human capital investment. Although we did not collect household-level consumption data, one category in which we can observe such a reduction is the household’s SHS consumption. The median household in the secured treatment group was locked on 1/4 of days during loan repayment, corresponding to a 25% reduction in SHS consumption compared to the control group. While the 25% reduction in SHS consumption likely overstates the loss in utility to households from being locked, the welfare loss due to being locked is not insignificant.

For additional evidence on the welfare effects, our endline survey asked a series of questions about financial shocks and household’s ability to cope with them (see Section ??). Notably, we found no evidence that the secured treatment group was more likely to experience shocks nor that their ability to cope with them was compromised (see Table[9]).

In summary, the evidence suggests that access to digitally secured school-fee loans increased school enrollment and human capital investment at the primary cost of a decrease in SHS consumption (and likely a modest decrease in other forms of consumption). Quantifying the welfare effects would require additional structure on the environment (e.g., households preferences, returns to education, etc.), which is beyond the scope of this paper. However, we believe that a structural estimation to identify the welfare effects of digitally collateralized loans is an important next step for future research.

8 Conclusion

In this paper, we explore a novel form of financial contracting that uses lockout technology to create digital collateral, which does not require physical repossession. Rather, the lender temporarily disables the flow value of the collateral to the borrower when the borrower misses a payment. We show that digitally collateralized loans exhibit significantly higher repayment

\footnote{As in the model, it is optimal for the household not to repay on days where their value for SHS is below a threshold value.}
and are therefore substantially more profitable to the lender. About one-third of the increase in repayment can be attributed to screening and about two-thirds to reducing moral hazard. Access to these loans had positive effects on educational outcomes and did not have negative effects on households’ balance sheet.

Our finding that moral hazard drives the majority of the repayment increase implies that credit provision is both sustainable and acceptable to a large fraction of households, provided they are given the right incentives. Therefore, the potential for digital collateral to expand access to credit is significant. By contrast, if we had found that adverse selection drove most of the increase in repayment, then digital collateral serves primarily as a screening device and only a select subset of households provide profitable lending opportunities.

Our field experiment also demonstrates the potential for private institutions to offer digitally collateralized loans to pay for schooling, resulting in increased enrollment and expenditures without placing a significant financial burden on the household. This result is important as schooling-related costs are large relative to income and must be paid in periods of low income for many households, especially those working in agriculture and other informal jobs.

There are numerous other potential applications in which digital collateral could be utilized to provide cheaper access to credit, which appear especially promising in economies with an underdeveloped banking and financial system. With the proliferation of smart devices, secured lending via digital collateral could easily be extended to a wide range of investments such as laptops, refrigerators, automobiles, and farming equipment. Importantly, the capacity to reuse collateral for future loans (as it has been by Fenix and PayJoy) expands the potential impact of the innovation as a vehicle for affordable access to credit. Many utility companies (e.g., electric, telecommunication, and water) are able to remotely disable service and thus natural candidates for offering credit secured by access to the flow of services they provide. We believe there is significant poten-
tial to further scale the use of digital collateral in providing affordable access to credit in LMICs.

Note: Standard errors in parentheses. Loan repayment is measured by the cumulative proportion of the loan principal repaid (Panel A). Loan completion describes whether the loan principal has been repaid (Panel B). The above results display the Local Average Treatment Effect (LATE), which measures the average treatment effect on loan repayment (completion) for compliers, using the share of days in compliance as the endogenous variable (see the Appendix for Intent to Treat (ITT) results). The analysis is run on samples at either the 100th, 110th, 150th, or 200th day from loan origination. “Lockout” captures the difference in the repayment (completion) rate between the Unsecured and Secured samples, “Adverse Selection” captures the difference in the repayment (completion) rate between the Unsecured and Surprise Unsecured samples, and “Moral Hazard” captures the difference in the repayment (completion) rate between the Surprise Unsecured and Secured samples. “p-value diff” records the p-value from testing the equality of the differences between the Adverse Selection and Moral Hazard LATE models. * p < .10, ** p < .05, *** p < .01

Note: Standard errors in parentheses. Loan repayment is measured by the cumulative proportion of the loan principal repaid. Loan completion describes whether the loan principal has been repaid. The above results display the Local Average Treatment Effect (LATE), which measures the average treatment effect on loan repayment (completion) for compliers, using the share of days in compliance as the endogenous variable (see the Appendix for Intent to Treat (ITT) results). The analysis is run on the sample at the 150th day (for loan repayment) or 200th day (for loan completion) from loan origination. Under “Lockout” where the subsample is those who were assigned Secured or Unsecured, “Treatment” captures the treatment effect of Secured. Under “Adverse Selection” where the subsample is those who were assigned Unsecured or Surprise Unsecured, “Treatment” captures the treatment effect of Surprise Unsecured. Under “Moral Hazard” where the subsample is those who were in assigned Surprise Unsecured and Secured, “Treatment” captures the treatment effect of Secured. “Median risk or above” is an indicator for whether the customer had their solar home system locked for 11 percent or more of its history by early May 2019, right before the start of the experiment. The × symbol signals an interaction between two variables. * p < .10, ** p < .05, *** p < .01
Figure 5: Effect of Lockout on Loan Take-up by Willingness to Pay

Note: This figure covers the sample of 950 individuals, of which 344 are treated with Secured loans and 606 are treated with Unsecured loans. Individuals treated with Surprise Unsecured loans are excluded from this figure. Individuals with willingness to pay to unlock next day of 0 or 1,000 UGX are in the first group, of 2,000 or 3,000 UGX in the second group, and of 4,000 or 5,000 in the third group. The differences in take-up between individuals treated with Secured and Unsecured loans are plotted and 95% confidence intervals are presented along with the bars. Note that 1 USD was equal to approximately 3,704 UGX in 2019 (Source: https://data.worldbank.org/indicator/PA.NUS.FCRF?locations=UG).

Note: Standard errors in parentheses. Results relate to Term 2 outcomes. The above results display the Local Average Treatment Effect (LATE), which measures the average treatment effect for compliers, using actual receipt of a school fee loan type (or any school fee loan) as the endogenous variable(s) (see the Appendix for Intent to Treat (ITT) results). “Enrollment” describes the share of school-aged children (SAC; individuals aged 5-20) enrolled in Term 2, and is conditional on having at least one SAC within the household at endline. “Days absent” describes the average days of school missed per month, per enrolled SAC, and is conditional on having at least one SAC enrolled at endline in Term 2. “School expenditures” (school fees, supplies, transport, and school meals) describes the average school expenditure per enrolled SAC and is conditional on having at least one SAC enrolled at endline in Term 2. School expenditures are in USD (1 USD is equal to approximately 3,704 UGX in 2019). School expenditures are winsorized at the 99th percentile. The outcome control mean for school expenditures is not log transformed. “p-value from F-test” records the p-value from the F-test that all treatment coefficients are equal. * $p < .10$, ** $p < .05$, *** $p < .01$

Note: Standard errors in parentheses. The above analysis uses the Intent to Treat (ITT) from loan assignment. Liquidity Shock Category A gathers together the following experiences over the last 6 months: not having enough money for basic needs such as food and clothing; not having enough money for other living home expenses; being unable to educate all of your children; not having enough money for medicines and medical treatment; debts owed to others. Liquidity Shock Category B gathers together the following experiences over the last 6 months: health problems or illness; an accident or disaster; difficulty finding work; death of a family member; job loss; weather affecting your crops. Columns (1) and (2) use the proportion of shocks within a category that one is said to have experienced over the last 6 months as the dependent variable. Columns (3) and (4) use the average value of the likert-scale values transformed to 0-1 scales, out of the shocks experienced within a category, as the dependent variable. The reference group is the Control group that was not assigned any school fee loan. * p < .10, ** p < .05, *** p < .01.

Note: Standard deviations in parentheses. The World Bank Uganda LSMS information in (1) comes from the 2018/2019 wave and uses probability weights. (2) and (3) come from Fenix administrative data. LSMS demographics relate to the household head, while Fenix demographics relate to the customer signing with Fenix. For Occupation using the Fenix data, “Agriculture or Non-employed” includes Cattle Trader, Farmer, Fisherman, and Not Employed; “Professional” includes Accountant, Banker, Broker, Electrician, Engineer, Government / Civil Servant, Health Worker, Journalist, Mechanic / Technician, NGO Worker, Office Work, Police, Security Guard, Teacher, Tour Guide, UPDF, and Uganda Prisons; “Non-professional” includes Boda Boda, Butcher, Carpenter, Construction, Driver, Herbalist, MM Agent, Market Trader, Money Changer, Religious Leader, Shop Keeper, Small Business Owner, Tailor, and Taxi Operator. LSMS sample occupations followed a similar categorization. (3) is a subset of (2). The results from tests of differences comparing (1) to (2) and (2) to (3) are displayed in (2) and (3), respectively. Menu of Choice treatment customers are dropped from (2) and (3), and comprised less than 2% of those samples. * p < .10, ** p < .05, *** p < .01

Note: Standard errors in parentheses. Loan repayment is measured by the cumulative proportion of the loan principal repaid (Panel A). Loan completion describes whether the loan principal has been repaid (Panel B). The above results display the Intent to Treat (ITT) analysis, which measures the average effect of treatment assignment on loan repayment (completion). The analysis is run on samples at either the 100th, 110th, 150th, or 200th day from loan origination. “Lockout” captures the difference in the repayment (completion) rate between the Unsecured and Secured samples, “Adverse Selection” captures the difference in the repayment (completion) rate between the Unsecured and Surprise Unsecured samples, and “Moral Hazard” captures the difference in the repayment (completion) rate between the Surprise Unsecured and Secured samples. “p-value diff” records the p-value from testing the equality of the differences between the Adverse Selection and Moral Hazard ITT models. * p < .10, ** p < .05, *** p < .01

</table>

Note: Standard errors in parentheses. The samples are further restricted to those individuals who had received the baseline survey after placing the loan deposit or who had not received a baseline survey (Early Adopters). Loan repayment is measured by the cumulative proportion of the loan principal repaid (Panel A). Loan completion describes whether the loan principal has been repaid (Panel B). The Intention to Treat (ITT) measures the average effect of treatment assignment on loan repayment (completion), while the Local Average Treatment Effect (LATE) measures the average treatment effect on loan repayment (completion) for compliers, using the share of days in compliance as the endogenous variable. The analysis is run on samples at either the 100th, 110th, 150th, or 200th day from loan origination. “Lockout” captures the difference in the repayment (completion) rate between the Unsecured and Secured samples, “Adverse Selection” captures the difference in the repayment (completion) rate between the Unsecured and Surprise Unsecured samples, and “Moral Hazard” captures the difference in the repayment (completion) rate between the Surprise Unsecured and Secured samples. “p-value diff” records the p-value from testing the equality of the differences between the Adverse Selection and Moral Hazard ITT models. * p < .10, ** p < .05, *** p < .01

</tbody>
</table>

Note: In this analysis, we exclude customers with imperfect compliance (i.e., customers who were supposed to be locked were unlocked for some days and vice versa). Loans in each treatment group are sorted by proportion of days locked at SMS and divided into equal-sized terciles. Loans in each tercile are formed into a portfolio. The internal rate of return (IRR) is the discount rate that makes the net present value of cash flows on the portfolio equal to zero. The IRRs of portfolios formed using all loans in each treatment group are also reported. The range of the fraction of days locked is reported in square brackets.

Figure A.1: Loan Repayment (Completion) by Percent of Days Locked on Day 150

Note: 95% confidence intervals (displayed with dotted lines) are obtained via bootstrapping. Percent of days locked at SMS is trimmed at 1% and 99%. Repayment (completion) rate on day 150 is residualized to remove the effects of treatments and recentralized to the mean of the Secured group.
Figure A.2: Loan take-up by willingness to pay

Note: This figure covers the sample of 950 individuals, of which 344 are treated with Secured loans and 606 are treated with Unsecured loans. Individuals treated with Surprise Unsecured loans are excluded from this figure. Individuals with willingness to pay to unlock next day being 0 or 1,000 UGX are in the first group, being 2,000 or 3,000 UGX in the second group, and being 4,000 or 5,000 in the third group. The average loan take-up by willingness to pay is plotted and 95% confidence intervals are along with the bars. Note that 1 USD was equal to approximately 3,704 UGX in 2019 (Source: https://data.worldbank.org/indicator/PA.NUS.FCRF?locations=UG).
A.2 Competitive Firms

When firms compete for households, they offer the contract that maximizes each household’s welfare subject to breaking even. That is, the contract offered to household $i$ solves

$$(d_i, p_i) \in \arg \max_{d, p} U_i(d, p)$$

subject to

$$\pi_i(d, p) \geq 0$$

Household expected utility is decreasing in both $d$ and $p$. However, the deposit is purely a transfer while a higher $p$ destroys more surplus. Therefore, to maximize household utility, firms minimize $p_i$ subject to breaking even.

**Proposition 5 (Competitive Equilibrium).** In a competitive equilibrium:

1. The household purchases the good if and only if condition (i) or (ii) from Proposition 4 is satisfied. Otherwise, there does not exist a contract such that both the firm breaks even and the household is willing to accept.

2. If the household purchases the good then $d_i^c = w$ and $p_i^c$ is the lowest price such that $R_i(p_i^c) = c - w$.

Notice that the household purchases under the exact same conditions as when the firm is a monopolist. Thus, Corollary 4 also holds with competitive firms and any implications for total surplus apply to both settings. Of course, the price offered by competitive firms is lower for all but the marginal household. Figure A.3 illustrates equilibrium quantities with competitive firms for the same parametric example as in Section 3.3.

![Graphs](https://ssrn.com/abstract=3821998)

(a) Low household wealth, $w = \frac{1}{12}$. 
(b) High household wealth, $w = \frac{1}{6}$.

Figure A.3: Illustrating the role of lockout with competitive firms.

A.3 Proofs

**Proof of Proposition 4**. Household $i$ strategically defaults with probability $(1 - q_i)F(p/\lambda)$, where $F(\cdot)$ is a cdf and therefore increasing in its argument. Fixing $p$, as $\lambda$ increases the argument, $p/\lambda$, decreases and therefore so too does $(1 - q_i)F(p/\lambda)$. 

\[ \square \]
Proof of Proposition 5. By hypothesis, \( S_1(p) = (1-\lambda)E(\hat{v}) < S_0(p) = \int_p^\infty \max\{v-p,1-\lambda\}dF(v) \). Hence, there must exist \( v \) such that the household does not strategically default (i.e., \( \bar{v} > p/\lambda \)) and therefore \( S_1(p) \) is strictly decreasing in \( q_i \). Further, observe that \( S_1(p) \) is continuous in \( q_i \). By the intermediate value theorem, there must exist a \( q_j \in (0,1) \) such that \( S_j(q) = d \leq w \). From (2), all \( i \) such that \( q_i \leq q_j \) will purchase and all \( i \) such that \( q_i > q_j \) will not. Hence, \( q_j = q \). To see that \( q \) is decreasing in \( \lambda \), differentiate both sides of \( S_j(q) = d \) with respect to \( \lambda \) to get that

\[
0 = \frac{dS_j(p)}{d\lambda} \quad \text{and} \quad \frac{\partial S_j}{\partial \lambda} + \frac{\partial S_j}{\partial q_j} \frac{\partial q_j}{\partial \lambda} 
\]

Hence, \( \frac{\partial S_j}{\partial q_j} = -\frac{\partial S_j}{\partial \lambda} \frac{\partial q_j}{\partial \lambda} < 0 \), since \( \frac{\partial S_j}{\partial \lambda} \leq q_j \). \( \square \)

Proof of Lemma 1. We will first show that \( d_i = w \) is optimal. First, clearly \( d_i < \min\{w,S_i(p_i)\} \) is suboptimal since the monopolist can simply increase \( d_i \) and earn more profit. Therefore, \( d_i = \min\{w,S_i(p_i)\} \). Next suppose that the monopolist sells to household \( i \) and \( d_i < w \), which therefore implies \( d_i = S_i(p_i) \) and therefore \( p_i \) solves \( \arg\max S_i(p_i)+R_i(p_i) - c \). Since repossession is inefficient (Assumption 2), total surplus is maximized by setting \( v(p) = \tilde{v} \) or \( p_h = \lambda \tilde{v} \), but then \( d_i + R_i(p_i) < w + R_i(\lambda \tilde{v}) \leq w + \lambda \tilde{v} < c \) (by Assumption 3). Thus, the monopolist would prefer not to sell to household \( i \), a contradiction. Hence, \( d_i = w \). \( \square \)

Proof of Proposition 3. As shown in Lemma 1, when \( w \leq S_i(p^*) \) then the monopoly price is \( p^* = \lambda \bar{v} \). Conditional on purchasing the good, the probability that household \( i \) strategically defaults is therefore \( (1-q_i)F(v^*) \). Thus, to prove the result, it suffices to show that \( v^* \) is increasing in \( \kappa \) and decreasing in \( \lambda \). The left-hand side of (9) is independent of the two parameters and increasing in \( v \) (by Assumption 4). The right-hand side of (9) is increasing in \( \kappa \) and decreasing in \( \lambda \). Thus, the point at which the left and right-hand side intersect (i.e., \( v^* \)) must increase with \( \kappa \) and decrease with \( \lambda \). \( \square \)

Proof of Proposition 4. This result follows from computing when monopoly profits are positive given the optimal prices in Lemma 1. For (i), when \( w < S_i(p^*) \), the firm’s total profit from selling to household \( i \) under the optimal contract is \( w + R_i(p^*) - c \). Similarly, for (ii), when \( w > S_i(p^*) \), the firms total profit from selling to household \( i \) is \( w + R_i(S_i^{-1}(w)) - c \). \( \square \)

Proof of Proposition 5. It is straightforward to argue that the constraint in (9) binds with equality. If not, then the firm could lower \( d \) and increase \( U_i \). We can therefore rewrite the program (9) as

\[
(d_i,p_i) = \arg\max_{d,p} U_i(d,p) + \pi_i(d,p)
\]

s.t. \( \pi_i(d,p) = 0 \) \hspace{1cm} (10)

Since \( d \) does not enter the objective of (10) and total surplus is decreasing in \( p \), the solution to the above involves the smallest \( p \) such that the firm makes zero profit (and then setting \( d_i = w \)), which is precisely as stated in (ii). Statement (i) then follows from computing when the firm profits are non-negative given the prices in (ii). \( \square \)
